containing MAG and Nogo (20). Thus, NgR must be considered a general receptor for restrictive effects of CNS myelin on axon growth in the adult mammalian CNS (Fig. 4C). Although MAG and Nogo-66 both bind to the LRRs of NgR, they appear to bind independently. This provides an explanation for similar but additive effects of Nogo and MAG on inhibition of axon growth. Evidence indicates that the NgR ligands, Nogo and MAG, are the two primary inhibitors in CNS myelin. Myelin prepared from mice lacking Nogo-A exhibits reduced inhibition of axon outgrowth, and the residual inhibitory activity is abolished by antibodies to MAG (22). Because one receptor mediates the action of both known myelin-derived inhibitors, interference with NgR function after CNS axonal injury may significantly alleviate myelin-dependent limitation of axonal regeneration.

Amphiphysin 2 (Bin1) and T-Tubule Biogenesis in Muscle
Eunkyung Lee,1* Melissa Marcucci,1* Laurie Daniell,1 Marc Pypaert,1 Ora A. Weisz,2 Gian-Carlo Ochoa,1 Khashayar Farsad,1 Markus R. Wenk,1 Pietro De Camilli1†

In striated muscle, the plasma membrane forms tubular invaginations (transverse tubules or T-tubules) that function in depolarization-contraction coupling. Caveolin-3 and amphiphysin were implicated in their biogenesis. Amphiphysin isoforms have a putative role in membrane deformation at endocytotic sites. An isoform of amphiphysin 2 concentrated at T-tubules induced tubular plasma membrane invaginations when expressed in nonmuscle cells. This property required exon 10, a phosphoinositide-binding module. In developing myotubes, amphiphysin 2 and caveolin-3 segregated in tubular and vesicular portions of the T-tubule system, respectively. These findings support a role of the bilayer-deforming properties of amphiphysin at T-tubules and, more generally, a physiological role of amphiphysin in membrane deformation.

Ultrastructural observations have suggested that T-tubules of striated muscle develop from beaded tubular invaginations of the plasma membrane that resemble strings of caveolae (1–2). Accordingly, recent studies have demonstrated a critical role for caveolin-3 in T-tubule biogenesis (3–5) and have implicated caveolin-3 in a form of human muscular dystrophy (6). However, the smooth tubular profile of the T-tubule system of mature muscles indicates that the function of caveolin is, at least in part, replaced by other proteins during muscle differentiation. In addition, T-tubules, albeit with an abnormal morphology, are present in mice lacking caveolin-3 (5), indicating that other proteins participate in tubulogenesis.

It was reported that a splice variant of amphiphysin 2 is expressed at very high levels in adult striated muscle [mature M-amphiphysin 2, also referred to as Bin1 (7, 8)] and is localized at T-tubules (7). Amphiphysin proteins function

as adaptors between the plasma membrane and submembranous cytosolic scaffolds (9). They contain a highly conserved NH2-terminal region (BAR domain), a COOH-terminal SH3 domain, and a variable central region (Fig. 1A). In amphi-physin 1 and in the predominant neuronal isoform of amphi-physin 2 (neuronal or N-amphi-physin 2), the central region contains binding sites for clathrin and adaptor protein-2 (AP-2), reflecting a role of these proteins in endocytosis (10–12). Such sites are not present in M-amphi-physin 2, which instead contains a unique exon (exon 10), just downstream of the BAR domain (7, 8). In vitro studies have shown that the BAR domain of amphi-physin binds and evaginates lipid membranes into narrow tubules (13–15) suggesting that M-amphi-physin 2 may generate membrane curvature in vivo and perhaps contribute to the biogenesis of T-tubules. Muscle T-tubule defects were detected in Drosophila that harbor mutations in its only amphi-physin gene (15).

To gain mechanistic insight into the properties of M-amphi-physin 2, we expressed green fluorescent protein (GFP)-tagged isoforms of amphi-physin 1 and 2 in Chinese hamster ovary (CHO) cells. In spite of the reported lipid-binding properties of amphi-physin in vitro (13), both amphi-physin 1 and N-amphi-physin 2 had, primarily, a diffuse cytosolic distribution. In contrast, M-amphi-physin 2 was highly concentrated at the cell surface (Fig. 1B). Plasma membrane targeting was mediated by the BAR domain and was dependent on exon 10 (Fig. 1). Exon 10 has a high basic amino acid content (9 out of 15, see Fig. 1A) and has an overall resemblance to phosphatidylinositol-4,5-bisphosphate [PI(4,5)P2]-binding amino acid sequences (16, 17). Binding of the BAR domain to liposomes was enhanced by the presence of exon 10 when liposomes contained PI(4,5)P2 [and to a lesser extent phosphatidylinositol-4-phosphate, PI(4)P] (Fig. 1C). Thus, the targeting of M-amphi-physin 2 to the plasma membrane is likely to be mediated by binding of its BAR domain, including exon 10 (BAR* domain), to PI(4)P and PI(4,5)P2. This result is consistent with the selective enrichment of PI(4,5)P2 in the plasma membrane (17).

Transfected CHO cells expressing full-length GFP-tagged M-amphi-physin 2 revealed an accumulation of numerous narrow tubular structures continuous with the plasma membrane as seen by electron microscopy (Fig. 2A) and by their accessibility to the membrane impermeable fluorescent dye FM4-64 (Fig. S1A). Furthermore, a GFP-tagged pleckstrin homology domain of phospholipase Cδ (PHPLCδ), a protein module that binds PI(4,5)P2 and thus acts as a plasma membrane marker (17), was targeted to these tubules when coexpressed with untagged M-amphi-physin 2 (Fig. S1A). Incubation of recombinant M-amphi-physin 2 with liposomes caused their exhaustion into tubules similar in size to those found in transfected cells (Fig. 2C). These results indicate that the powerful liposome tubulating activity of amphiphysin observed in vitro (13–15) is a property that is relevant in vivo.

Dynamin 2, a binding partner of the SH3 domain of amphiphysin (9), was recruited to the tubules when coexpressed with M-amphi-physin 2 (Fig. 2D), but not when coexpressed with its BAR* domain, which was sufficient to induce tubulation (Fig. 2, B and E). Endogenous dynamin 2 was also partially recruited to the tubules by M-amphi-physin 2, but not by the
BAR* domain (insets of Fig. 2, D and E, respectively). Tubules induced by the BAR* domain alone were often closely opposed to each other (Fig. 2B), whereas those induced by full-length M-amphiphysin 2 were always separated by cytoplasmic matrix (Fig. 2A), possibly reflecting the presence of a protein scaffold including dynamin 2.

We investigated the temporal and spatial expression pattern of M-amphiphysin 2 during muscle differentiation using the C2C12 myoblastic cell line. Expression of amphiphysin 2 increased upon differentiation, as previously reported (18), and correlated with increased expression of caveolin (3–5) and the dihydropyridine receptor (DHPR) (18), a Ca\(^{2+}\) channel of T-tubules (19), and with the down-regulation of caveolin-1 (Fig. 3A). Immunofluorescence staining for M-amphiphysin 2 in differentiated C2C12 cells produced a staining pattern represented by linear elements reminiscent of those seen in M-amphiphysin 2-expressing fibroblasts (Fig. 3B). DHPR-immunoreactive puncta were aligned with these elements. Caveolin-3 immunostaining was often aligned with these tubules but in a discontinuous fashion (Fig. 3C). Electron microscopy of differentiated C2C12 myotubes after cytochemical staining of cell-surface membranes with either ruthenium red

Fig. 2. In vivo and in vitro tubulation of lipid membranes by M-amphiphysin 2. (A and B) Electron microscopic views of transfected CHO cells expressing either M-amphiphysin 2 (A) or its BAR* domain (B) reveal the presence of narrow tubules continuous with the plasma membrane [inset of (A)]. (C) Electron micrograph demonstrating the massive tubulation of liposomes induced by recombinant M-amphiphysin 2. (D and E) GFP–dynamin 2 is recruited to tubules when co-expressed with untagged full-length M-amphiphysin 2 (D), but not when co-expressed with the BAR* domain, which lacks the SH3 domain (E). In these two fields, M-amphiphysin 2 and BAR* domain were detected by immunofluorescence. Insets of (D) and (E) show endogenous dynamin immunoreactivity in cells transfected with GFP–M-amphiphysin 2 full-length and GFP–BAR*, respectively. (F) Double immunofluorescence for caveolin-1 and amphiphysin of M-amphiphysin 2–transfected CHO cells. Caveolin-1 immunoreactivity (red) is detectable in a punctate pattern along M-amphiphysin 2–positive tubules (green). Scale bars, 200 nm in (A to C) and 20 \(\mu\) m in (f).

Fig. 3. Amphiphysin 2, DHPR, and caveolin in C2C12 cells. (A) Comparative analysis of the expression of amphiphysin 2, DHPR, caveolin-1, and caveolin-3, during cell differentiation. (B and C) Immunofluorescence microscopy of differentiated C2C12 myotubes demonstrating localization of endogenous amphiphysin 2 on tubular elements and partial overlap of amphiphysin 2 with DHPR and caveolin-3. The insets of (B) and (C) show that puncta of DHPR and caveolin-3 immunoreactivity are often aligned with amphiphysin 2–positive tubules. The images of (C) were obtained by confocal microscopy. (D) Electron micrograph of differentiated C2C12 myotubes after incubation with ruthenium red demonstrates the presence of deep, tubulovesicular plasma membrane invaginations (arrow). Localisation of amphiphysin 2 (E) and caveolin-3 (F) in ultrathin frozen section of differentiated C2C12 myotubes as revealed by single immunogold labeling. (G to I) Samples prepared as in (E) and (F), but double-labeled for M-amphiphysin 2 (small gold) and caveolin-3 (large gold). In (E to I), amphiphysin 2 and caveolin-3 are concentrated on the tubular and vesicular portion, respectively, of the HRP-labeled network. Scale bars, 10 \(\mu\) m in (B) and (C), 200 nm in (D to I).
(20) (Fig. 3D) or horseradish peroxidase (HRP)-conjugated cholera toxin (3) revealed, as expected, a prominent network of surface-connected tubulovesicular structures (Fig. 3, E to I). Single (Fig. 3, E and F) and double (Fig. 3, G to I) immunogold labeling of ultrathin frozen sections of these cells revealed that the tubular portion of the network was intensely immunoreactive for amphiphysin 2, whereas caveolin-3 was preferentially concentrated on its vesicular domains. The segregation of caveolin-3 and amphiphysin 2 was amplified in adult skeletal muscle, where amphiphysin 2 was selectively localized on T-tubules, whereas caveolin-3 was primarily concentrated at the outer surface of the muscle fiber as previously reported (6, 21).

As M-amphiphysin 2–induced membrane tubules of transfected cells (fig. S1A), endogenous tubules of C2C12 cells accumulated GFP-PH(PC, Fig. 4A), suggesting a high PI(4,5)P2 content. If T-tubules are PI(4,5)P2-positive, their massive proliferation during the differentiation of C2C12 cells should correlate with a prominent network of surface-connected tubulovesicular structures (Fig. 3, E and F) immunogold labeling of ultra-thin frozen sections of these cells (fig. S4). Indeed, the phosphoinositide content of differentiated C2C12 cells was amplified in adult skeletal muscle, where amphiphysin 2 was selectively localized on T-tubules of C2C12 cells (22).

In agreement with the role of caveolin and caveolae in early stages of T-tubule biogenesis, cholesterol depletion by amphotericin B was shown to impair T-tubule formation in C2C12 cells (23). Accordingly, we found that exposure of C2C12 cells to either methyl β-cyclodextrin (24) or amphotericin B disrupted the pattern of amphiphysin 2 and caveolin-3 immunoreactivity (fig. S3 and (21)). In view of these observations, we also examined the relationship between M-amphiphysin 2–induced tubules, caveolin-1 [the major isoform of caveolin in fibroblasts (25)], and cholesterol in transfected CHO cells expressing M-amphiphysin 2. As in the case of caveolin-3 immunoreactivity in C2C12 cells, caveolin-1 puncta were often aligned with M-amphiphysin 2 tubules (Fig. 2F). In addition, cyclodextrin-mediated cholesterol depletion led to a collapse of the tubules (fig. S2, A and B). These findings reveal additional similarities between plasma membrane invaginations induced by M-amphiphysin 2 in fibroblastic cells and bona fide muscle T-tubules. Collectively, our results indicate that expression in fibroblasts of a single protein, M-amphiphysin 2, is sufficient to induce a tubular network that shares some morphological and biochemical similarities with T-tubules of muscle.

To study more directly whether amphiphysin 2 is required for T-tubule development, we suppressed its expression by RNA interference (RNAi) (26). Two pairs of small interfering RNA or silencing RNA (siRNA) specific for amphiphysin 2 were transfected into C2C12 cells before their differentiation. Both pairs, either separately or together, almost completely blocked the expression of amphiphysin 2 and reduced the expression of caveolin-3 without affecting expression of dynamin 2 (fig. S4). More generally, they inhibited myoblast fusion and differentiation under these in vitro conditions [fig. S4B and (21)], which is consistent with results obtained by partial disruption of amphiphysin 2 expression by means of the antisense RNA technique (18). Although this effect of amphiphysin 2 suppression did not allow us to assess the role of M-amphiphysin 2 in the context of a mature myotube, it emphasized the important role of amphiphysin 2 in muscle differentiation.

The role of caveolin-3 in the biogenesis of T-tubules is complemented by amphiphysin during T-tubule maturation. Additional factors are likely to contribute to the morphology of mature T-tubules, because in amphiphysin Dro sophila mutants the T-tubule system is abnormal but not absent (15). The results of this study provide evidence for a physiological function of the membrane-deforming properties of amphiphysin and for a role of alternative splicing in determining its sites of action. The clathrin- and AP-2–binding domains present in mammaalian amphiphysin 1 and in N-amphiphysin 2, target amphiphysin to clathrin-coated pits, where amphiphysin may assist in the generation of membrane tubules (13). Except for the T-tubule membrane, the cell compartment where the bulk of PI(4,5)P2 is localized. The high concentration of M-amphiphysin 2 at the plasma membrane, in turn, results in massive tubular invagination. Thus, the BAR domain may be used in two different cellular contexts, but with similar roles in membrane morphogenesis. It will be of interest to determine the role of the SH3-mediated interactions of amphiphysin in T-tubule physiology.
